Overview

This paper proposes Băhēm; a symmetric cipher that, when given a random-looking key \( k \), a true random number generator (TRNG) and a cleartext message \( m \) to encrypt, no cryptanalysis can degrade its security below \( \min(H(m), H(k)) \) bits of entropy, even under Grover’s algorithm [1] or even if it turned out that \( P = NP \).

Aside from the cost of memory access and input/output processing, Băhēm is also highly parallelisable, and requires only three additions and one bitwise exclusive-or operation (XOR) in order to encrypt or decrypt.

Its early prototype, Alyal, achieved similar run-time speeds to OpenSSL’s ChaCha20 [2]; slightly faster decryption, while slightly slower encryption when the TRNG was prepared in a file in advance. Future versions, with better TRNG optimisations, should be able to enable the prototype to have faster run-time for both, encryption and decryption, alike. Either way, Alyal is highly practical, specially when considering its strong security guarantee. Further speed gain is possible when Alyal utilises Băhēm’s high parallelism.

Notation

\( H(x) \): Shannon’s entropy of random variable \( x \).

\( x + y \mod 2^{128} \): Unsigned 128-bit addition.

\( \text{random}(128) \): A sequence of 128 many random bits generated by a TRNG.

\( k \): A 128-bit pre-shared secret key with enough \( H(k) \) that looks random. Ideally \( k = \text{random}(128) \).

\( m \): An arbitrarily-long cleartext message of \( |m| \) many bits.

\( \lfloor \frac{|m|}{128} \rfloor \): Number of 128-bit blocks in cleartext \( m \).

\( m_b \): The \( b \)th 128-bit block from \( m \).

\( p_b, q_b, m_b \): A pair of uniformly distributed random bits.

\( \hat{p}_b, \hat{q}_b, \hat{m}_b \): Encrypted forms of \( p_b \), \( q_b \) and \( m_b \), respectively.

1 Proposed Algorithm

Algorithms 1 and 2 show Băhēm’s encryption and decryption by which the process is repeated over every 128-bit blocks of \( m \).

Algorithm 1: Băhēm encryption

\[
\text{input} : k, m_0, m_1, \ldots \\
\text{output} : (\hat{p}_0, \hat{q}_0, \hat{m}_0), (\hat{p}_1, \hat{q}_1, \hat{m}_1), \ldots \\
\text{for } b \in (0, 1, \ldots, \lfloor \frac{|m|}{128} \rfloor - 1) \text{ do} \\
p_b \leftarrow \text{random}(128) \\
q_b \leftarrow \text{random}(128) \\
\hat{p}_b \leftarrow p_b + k \mod 2^{128} \\
\hat{q}_b \leftarrow q_b + k \mod 2^{128} \\
\hat{m}_b \leftarrow m_b \oplus (p_b + q_b \mod 2^{128})
\]

Algorithm 2: Băhēm decryption

\[
\text{input} : k, (\hat{p}_0, \hat{q}_0, \hat{m}_0), (\hat{p}_1, \hat{q}_1, \hat{m}_1), \ldots \\
\text{output} : m_0, m_1, \ldots \\
\text{for } b \in (0, 1, \ldots, \lfloor \frac{|m|}{128} \rfloor - 1) \text{ do} \\
p_b \leftarrow \hat{p}_b - k \mod 2^{128} \\
q_b \leftarrow \hat{q}_b - k \mod 2^{128} \\
m_b \leftarrow m_b \oplus (p_b + q_b \mod 2^{128})
\]

2 Security Analysis

The Bähem encryption is essentially the XOR cryptosystem:

\[
\hat{m}_b \leftarrow m_b \oplus (p_b + q_b \mod 2^{128})
\]

Encryption pad

It trivially follows from Shannon’s perfect secrecy proof of the one-time pad (OTP) [3] that Bähem is secure if and only if its encryption pad maintains its key’s entropy as shown in eq. (1), even if the adversary knows \(\hat{p}_b, \hat{q}_b, \hat{m}_b\) and the cleartext message \(m_b\).

\[
\begin{align*}
H(k|\hat{p}_b, \hat{q}_b, \hat{m}_b, m_b) &= H(k|\hat{p}_b, \hat{q}_b, p_b + q_b \mod 2^{128}) \\
&= H(k) \tag{1}
\end{align*}
\]

To simplify the analysis, suppose that the size of a block in Bähem is 3 bits only, and that the cleartext block \(m_b\) is known to the adversary, which implies that the adversary can trivially know that:

\[
p_b + q_b \mod 2^3 = \hat{m}_b \oplus m_b
\]

in addition to adversary’s knowledge of the public variables \(\hat{p}_b\) and \(\hat{q}_b\). More specifically, suppose that the adversary found that:

\[
\begin{align*}
0 &= \hat{p}_b = p_b + k \mod 2^3 \\
3 &= \hat{q}_b = q_b + k \mod 2^3 \\
5 &= p_b + q_b \mod 2^3
\end{align*}
\]

Then, the question is: will this information reduce the space from which the key \(k\) is chosen from? In other words, what are the possible values of \(k\) that can lead to the outputs 0, 3 and 5 above? Table 1 visualises this.

As shown in table 1, the total number of horizontal, or vertical, intersections that simultaneously cross all of the outputs 0, 3 and 5, remain \(2^3\). Meaning, the total number of values of \(k\) that could lead to the outputs remains \(2^3\).

This 3-bit example can be trivially extended by induction to show that the same conclusions hold even with a 128-bit unsigned addition and any other output numbers than 0, 3 and 5.

Therefore, we can conclude that adversary’s knowledge of the public variables \(\hat{p}_b, \hat{q}_b, \hat{m}_b\) and the cleartext \(m_b\), which leads to deducing \(p_b + q_b \mod 2^{128}\), can not reduce \(H(k)\).

Since Bähem is an XOR cryptosystem, and since its encryption pad is secure (theorem 2.1), therefore it has to follow by Shannon’s perfect secrecy [3] that Bähem’s encryption is secure as well.

**Theorem 2.1** (Secure encryption pad). If the key \(k\) looks like a uniformly distributed 128-bit random number, and \(p_b\) and \(q_b\) are 128-bit random numbers generated by a TRNG, then Bähem guarantees that its encryption pad satisfies:

\[
H(k|\hat{p}_b, \hat{q}_b, \hat{m}_b, m_b) = H(k)
\]

Bähem’s key space, therefore no cryptanalysis can reduce Bähem’s security below \(H(k)\).

**Theorem 2.2** (Secure encryption).

\[
H(m_b|\hat{p}_b, \hat{q}_b, \hat{m}_b) = \min(H(m_b), H(k))
\]

**Note 2.1.** Bähem does not have perfect secrecy, as this requires an impractical key that is as long as the message itself. Bähem rather has a \(H(k)\)-bit security. Shannon’s proof of perfect secrecy of the OTP is cited only for its relevance in proving Bähem’s \(H(k)\)-bit security as there are XOR cryptosystems.

3 Implementation Examples

3.1 C Functions

In this example, the caller is expected to initialise a 128 bits key \(k\), a pair of random pads, \(p\) and \(q\), each of which is \(1\text{en} \times 64\) bits long, in order to encrypt a \(1\text{en} \times 64\) bits long cleartext message m. The encryption happens in-place, so the caller does not have to allocate separate memory for the ciphertext.
void baheem_enc(
    uint64_t *k, /* 128bit pre-shared key */
    uint64_t *p, /* random pad 1 */
    uint64_t *q, /* random pad 2 */
    uint64_t *m, /* message */
    size_t len /* length of m = p = q */
) {
    size_t i;
    for (i = 0; i < len; i++) {
        m[i] ^= p[i] + q[i];
        p[i] += k[0];
        q[i] += k[1];
    }
}

Likewise, the following is an example implementing the corresponding in-place decryption function.

void baheem_dec(... same input ...) {
    size_t i;
    for (i = 0; i < len; i++) {
        p[i] -= k[0];
        q[i] -= k[1];
        m[i] ^= p[i] + q[i];
    }
}

3.2 A File Encryption Tool

Alyal is an single-threaded implementation to demonstrate Bâhêm’s practical utility with real-world scenarios. Internally, Alyal uses the baheem_enc and baheem_dec functions that were presented earlier in this section.

3.2.1 Installation

> git clone http://gitlab.com/rajululkahf/alyal
> cd alyal
> make test
> dd bs=1MB count=500 if=/dev/zero of=test.txt
> ./alyal enc test.txt test.enc
> ./alyal dec test.enc test.enc.txt
> shasum *

3.2.2 Benchmark

This benchmark that was performed on a machine with a 3.4GHz Intel Core i5-3570K CPU, 32GB RAM, 7200 RPM hard disks, Linux 5.17.4-gentoo-x86-64, and OpenSSL 1.1.1n.

Table 2 shows that, while the early Bâhêm prototype, Alyal, has a faster decryption run-time than OpenSSL’s ChaCha20, it has slower encryption run-time. However:

1. The differences in run-time are insignificant for most applications, which proves Bâhêm’s practical utility in the real world.
2. Bâhêm’s provable security should arguably justify waiting the 3 extra seconds for the 500MB data, specially that many user applications involve encrypting much smaller data sizes with unnoticeable time difference
3. Preparing the random bits in advance significantly reduces the encryption time as shown with the file.rand case in table 2, and can be optimised further should it be prepared in memory.
4. Alyal is currently single-threaded despite Bâhêm’s capacity for high parallelism as all blocks are independent. This gives room for future versions to be significantly faster.

4 Conclusions

This paper proposed Bâhêm with the following properties:

Secure. No cryptanalysis can degrade its security below min(H(m), H(k)) bits.

Fast. Requires only three additions and a single XOR per encryption or decryption alike.

Highly parallelisable as the encryption, or decryption, of any bit is independent of other bits. Bâhêm’s single-threaded prototype (Alyal) outperformed OpenSSL’s ChaCha20 when decrypting files, despite Bâhêm’s 2 bits overhead, which
demonstrates that such overhead is negligible in practice.

While the prototype has a slower encryption runtime due to its use of a TRNG, optimising it is trivial by preparing the TRNG in advance.

**Simple.** Bähèm’s simplicity implies fewer expected number of implementation bugs, and therefore higher practical security.
