Abstract

Localization of the stress-induced martensitic phase transformation plays an important role in the fatigue behavior of shape memory alloys (SMAs). The phenomenon of return-point memory that is observed during the subloop deformation of a partially-transformed SMA is a clear manifestation of the interaction between localized transformation and degradation of the functional properties. The goal of the present study is to demonstrate this structure–material interaction through modeling the phenomenon of return-point memory. A gradient-enhanced model of functional fatigue is developed for this purpose. The model is first employed to reproduce the hierarchical return-point memory in a pseudoelastic NiTi wire under isothermal uniaxial tension with nested subloops. Additionally, a more detailed analysis is carried out for a NiTi strip with more complex transformation pattern. Our study highlights on the subtle morphological changes of the phase transformation under different loading scenarios and resulting implications on the cyclic degradation and return-point memory.

Keywords: Phase transformation; Propagating instabilities; Functional fatigue; Subloop deformation; Finite-element method

1. Introduction

The practical interest in shape memory alloys (SMAs), especially NiTi, stems from their unique characteristics of pseudoelasticity and shape memory effect (Otsuka and Wayman, 1998; Mohd Jani et al., 2014). The operational lifespan of SMAs in most of the applications involves enduring cyclic mechanical/thermal loadings, which highlights the great importance of identifying their fatigue behavior. It is well-recognized that, due to the martensitic phase transformation, fatigue in SMAs is more complex than in common engineering metals. This complexity necessitates special attention

and, as a result, has prompted a tremendous number of studies that focus on the fatigue characterization of SMAs from a variety of perspectives and on the underlying micromechanical processes (Eggeler et al., 2004; Pelton, 2011; Mahtabi et al., 2015; Kang and Song, 2015; Zheng et al., 2017; Nargatti and Ahankari, 2022).

Stress-induced martensitic transformation in pseudoelastic NiTi appears (typically, in tension-dominated loadings) as localized instabilities in the form of martensite bands, and subsequently progresses via propagation of the instabilities in the form of patterned interfaces (macroscopic transformation fronts) that separate the domains of low-strained austenite and high-strained martensite (e.g., Shaw and Kyriakides, 1997b,a; Sun and Li, 2002; Reedlunn et al., 2014). Due to the high strain incompatibilities that exist within the transformation front and the ensuing large local stresses, it can be reasonably inferred that propagating instabilities can vitally influence both the functional fatigue and structural fatigue of the material. Despite the longstanding recognition of this crucial aspect (Lin et al., 1994; Lim and McDowell, 1994; Iadicola and Shaw, 2002; Eggeler et al., 2004; Brinson et al., 2004), its direct validation was provided only a few years ago in the experiments conducted by Zheng et al. (2016a,b, 2017). It was demonstrated that in view of the repetitive nucleation and propagation of the localized transformation in NiTi strips under cyclic uniaxial tension, a rapid degradation of pseudoelasticity occurs that accelerates the fatigue crack initiation and fatigue failure.

An interesting manifestation of the interaction between propagating instabilities and functional fatigue is found in the subloop deformation behavior of a partially-transformed SMA specimen under deformation-controlled loading. The subloop behavior has been extensively investigated experimentally, notably for NiTi (Lin et al., 1994; Lim and McDowell, 1994; Tobushi et al., 2003; Doraiswamy et al., 2011; Takeda et al., 2012) but also for other SMAs (Ortin, 1991; Müller and Xu, 1991). Fig. 1(a), reproduced from Tobushi et al. (2003), depicts the global mechanical response of a NiTi wire subjected to subloop paths. For a more intuitive description of the phenomenon, hypothetical schematics of the corresponding transformation front evolution are provided in Fig. 1(b). As the front propagates along the wire, it leaves behind transformation-induced microstructural defects, such as dislocations and stabilized (locked-in) martensite. During the subloop unloading (for instance, the first subloop, which starts at point A), the front travels backward over an already swept zone (from A to B), hence intensifying the generated defects. Accordingly, during the subloop reloading, the propagation of the front over the twice-swept zone occurs with a lower stress level compared to the original transformation plateau. When the front enters the pristine zone (at point A), the stress passes through the subloop unloading point and catches up with the original plateau. This trait is known as the return-point memory. The process repeats in the subsequent subloops and culminates in an intriguing hierarchical return-point memory.

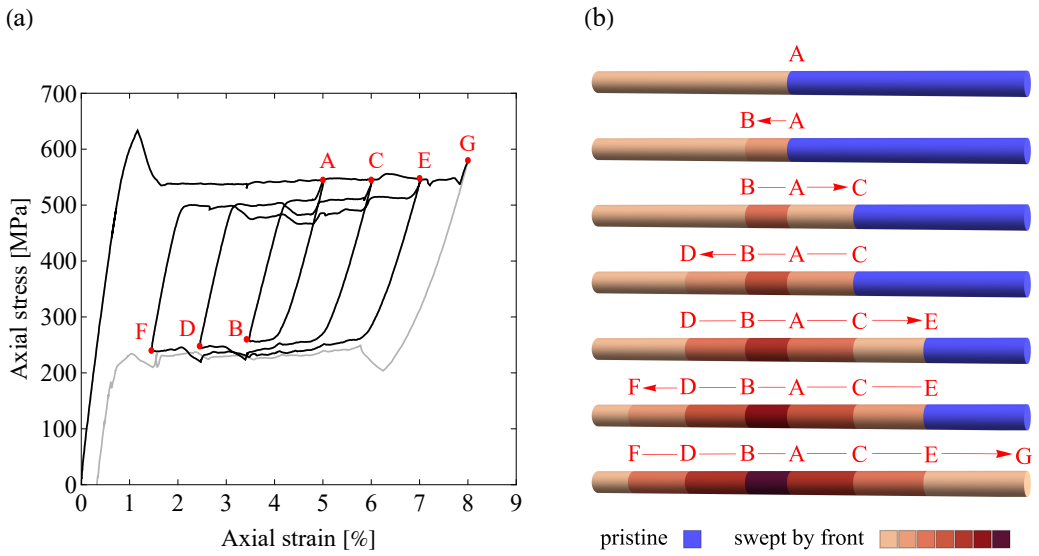

Figure 1: Return-point memory in NiTi wire subjected to uniaxial tension with three nested subloop paths: (a) the structural stress–strain response, and (b) hypothetical schematics of the corresponding transformation front evolution. The stress–strain response in panel (a) is reproduced from Tobushi et al. (2003) (courtesy of R. Matsui). The red arrows in panel (b) indicate the trajectory of the front propagation, and the color scales quantify the recurrence of the front's traversal over the wire's segments.

Motivated by the experimental results, numerous attempts have been made to develop SMA models capable of capturing the phenomenon of return-point memory during the subloop deformation, either through incorporating fatigue inelastic mechanism and degradation of functional properties (Savi and Paiva, 2005; Saint-Sulpice et al., 2009; Chan et al., 2012; Bartel et al., 2017) or by merely refining the constitutive equations of non-fatigue model of pseudoelasticity (Bouvet et al., 2004; Stupkiewicz and Petryk, 2010; Doraiswamy et al., 2011). In fact, a physically-relevant approach for modeling the return-point memory should hinge on the interaction between the propagating instabilities (structural inhomogeneities) and the functional fatigue of the material. Nevertheless, most of the existing models (including those referenced above) postulate a homogeneous martensitic phase transformation, while addressing a problem with a transformation of localized nature. Albeit this simplifies the computations significantly, it is not a plausible assumption in the present context. To the best of our knowledge, the only related modeling study that has accounted for this structure–material interaction is the 1D model of Bartel et al. (2017). In their model, however, instabilities do not originate from a softening-type intrinsic material response but are rather treated as weak displacement discontinuities that separate the transformed and untransformed material points (indeed, experiments (e.g., Hallai and Kyriakides, 2013) have confirmed that the true intrinsic response of NiTi is characterized by a significant softening branch). It should be remarked that recently Xiao and Jiang (2020, 2022) have acknowledged this structure–material interaction in

their simulations, however, their applications did not specifically pertain to the subloop deformation and return-point memory.

In light of the above premise, this work aims to provide a detailed modeling study of the phenomenon of return-point memory with an emphasis on the interaction between the propagating instabilities and the degradation of the functional properties of the material. A phenomenological gradient-enhanced model of functional fatigue is thus developed and is applied to the problem of subloop deformation in NiTi wire and strip under uniaxial tension. In what follows, we first introduce the model in Section 2. Then, in Section 3, the simulation results are presented and discussed. In addition, a simplified 1D version of the model is also provided in Appendix A.

2. A small-strain model of functional fatigue

The present functional fatigue model is formulated in the framework of the energy minimization principle. The basic structure of the model is adopted from the non-gradient model of pseudoelasticity developed by Stupkiewicz and Petryk (2013), while the gradient enhancement, micromorphic regularization and thermomechanical coupling are simply borrowed from our previous gradient-enhanced model. The latter has proved to be capable of reproducing complex patterns of phase transformation in different loading conditions (Rezaee-Hajidehi et al., 2020; Rezaee-Hajidehi and Stupkiewicz, 2021, 2023).

Functional fatigue is here treated in a simple phenomenological manner, and thus the constitutive relations are tailored to mimic the pseudoelasticity degradation effects. Since the focus of this study revolves around the macroscopic modeling of the return-point memory, a phenomenological formulation seems to adequately fulfill the intended purpose. In Section 2.1, we introduce the constitutive model in an isothermal format. Subsequently, in Section 2.2, micromorphic regularization, thermomechanical coupling and finite-element implementation are briefly discussed.

2.1. Constitutive model

We begin the model description by noting that functional fatigue in SMAs is typically attributed to a number of mechanisms. Among them, generation of dislocation slip (Eggeler et al., 2004; Delville et al., 2011), formation of stabilized martensite (Brinson et al., 2004; Zhang et al., 2019) and non-transforming austenite (Sedmák et al., 2015; Zhang et al., 2019) are the most likely involved mechanisms. In the present model, a detailed subdivision into the possible mechanisms and their mutual interaction is not attempted, instead, they are unitedly represented by phenomenological evolution equations, and are directly linked to the martensitic phase transformation through the accumulated martensite volume fraction η^{acc}. In line with this notion, fatigue mechanism is herein denoted as transformation-induced plasticity (TRIP).

The model is confined to small-strain theory. The material state at each point is characterized by two quantities, namely the total strain $\boldsymbol{\varepsilon} = \frac{1}{2}\left(\nabla \boldsymbol{u} + (\nabla \boldsymbol{u})^{\mathrm{T}}\right)$, with $\boldsymbol{u}$ as the displacement vector, and the martensite volume fraction η. The total strain is additively decomposed into

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^{\mathrm{e}} + \boldsymbol{\varepsilon}^{\mathrm{t}} + \boldsymbol{\varepsilon}^{\mathrm{p}}, \tag{1}$$

where $\boldsymbol{\varepsilon}^{\mathrm{e}}$ denotes the elastic contribution, $\boldsymbol{\varepsilon}^{\mathrm{t}}$ denotes the martensitic transformation contribution and $\boldsymbol{\varepsilon}^{\mathrm{p}}$ is the permanent strain associated with TRIP. At the same time, it is assumed that during the martensitic transformation a fraction of martensite stabilizes and does not transform back to austenite. Hence, the martensite volume fraction η is split into the reversible part η^{rev} and irreversible part η^{ir}, viz.,

$$\eta = \eta^{\mathrm{rev}} + \eta^{\mathrm{ir}}, \tag{2}$$

and the following inequality constraints hold,

$$0 \leq \eta^{\mathrm{ir}} \leq \eta \leq 1 \quad \Longrightarrow \quad 0 \leq \eta^{\mathrm{rev}} \leq 1 - \eta^{\mathrm{ir}}. \tag{3}$$

The material is in the fully austenitic state when $\eta = \eta^{\mathrm{rev}} = 0$ and is in the fully martensitic state when $\eta = 1$. Nevertheless, once the material starts transforming to martensite from a pristine austenitic state, η^{ir} becomes immediately nonzero, as indicated by Eqs. (4)–(6) below, and thereby, a fully austenitic state will not be recoverable.

It has been repeatedly observed in the experiments that the degradation of pseudoelasticity in conventional polycrystalline NiTi are mostly pronounced during the first tens of cycles, gradually diminishing and eventually reaching saturation as the material passes the so-called shakedown stage. In view of this general consensus, we adopt the assumption that both the irreversible volume fraction η^{ir} and the permanent strain $\boldsymbol{\varepsilon}^{\mathrm{p}}$ follow exponential-type evolution laws. Note that this assumption is not unique to the present model and has been exploited in various SMA functional fatigue models (e.g., Zaki and Moumni, 2007; Kan and Kang, 2010; Scalet et al., 2021; Xiao and Jiang, 2020). With this assumption in place, we first introduce the accumulated volume fraction η^{acc} as

$$\dot{\eta}^{\mathrm{acc}} = |\dot{\eta}^{\mathrm{rev}}| \quad \Longrightarrow \quad \eta^{\mathrm{acc}} = \int_0^t |\dot{\eta}^{\mathrm{rev}}| \, \mathrm{d}\tau, \tag{4}$$

where the overdot denotes the rate of change of the variable and t denotes the time. The evolution equation for the irreversible volume fraction η^{ir} is then explicitly postulated as

$$\eta^{\mathrm{ir}} = h_{\mathrm{ir}}^{\mathrm{sat}}(1 - \exp(-C_{\mathrm{p}}\eta^{\mathrm{acc}})), \tag{5}$$

which results from the time-integration of the following rate equation (with $\eta^{\mathrm{acc}}\big|_{t=0} = 0$ and $\eta^{\mathrm{ir}}\big|_{t=0} = 0$ as the initial conditions),

$$\dot{\eta}^{\mathrm{ir}} = h_{\mathrm{ir}}^{\mathrm{sat}} C_{\mathrm{p}} \exp(-C_{\mathrm{p}}\eta^{\mathrm{acc}})\dot{\eta}^{\mathrm{acc}}. \tag{6}$$

Analogously, the evolution equation for the permanent strain $\boldsymbol{\varepsilon}^{\mathrm{p}}$ is postulated as

$$\dot{\boldsymbol{\varepsilon}}^{\mathrm{p}} = \epsilon_{\mathrm{p}}^{\mathrm{sat}} C_{\mathrm{p}} \exp(-C_{\mathrm{p}} \eta^{\mathrm{acc}}) \dot{\eta}^{\mathrm{acc}} \boldsymbol{N}_{\mathrm{p}}. \tag{7}$$

In Eqs. (5)–(7), $h_{\mathrm{ir}}^{\mathrm{sat}}$ and $\epsilon_{\mathrm{p}}^{\mathrm{sat}}$ represent the respective saturation values for irreversible volume fraction and permanent strain, C_{p} is the degradation rate, and $\boldsymbol{N}_{\mathrm{p}}$ is the direction tensor which is defined such that the rate of the permanent strain $\dot{\boldsymbol{\varepsilon}}^{\mathrm{p}}$ is aligned with the martensitic transformation strain $\boldsymbol{\varepsilon}^{\mathrm{t}}$, i.e.,

$$\boldsymbol{N}_{\mathrm{p}} = \frac{\boldsymbol{\varepsilon}^{\mathrm{t}}}{\|\boldsymbol{\varepsilon}^{\mathrm{t}}\|}, \quad \|\boldsymbol{\varepsilon}^{\mathrm{t}}\| = \sqrt{\mathrm{tr}(\boldsymbol{\varepsilon}^{\mathrm{t}})^2}. \tag{8}$$

Note that, in view of the definition of the accumulated volume fraction η^{acc}, the variables η^{ir} and $\boldsymbol{\varepsilon}^{\mathrm{p}}$ evolve continuously during both the forward and backward transformations.

Martensitic transformation in SMAs usually exhibits negligible volumetric change (Bhattacharya, 2003). The transformation strain $\boldsymbol{\varepsilon}^{\mathrm{t}}$ is therefore assumed to be deviatoric (i.e., $\mathrm{tr}\,\boldsymbol{\varepsilon}^{\mathrm{t}} = 0$). Moreover, since the stress-induced transformation renders the martensite variants to be oriented in the direction of the applied stress, martensite is here considered to appear in a fully-oriented state so that the transformation strain $\boldsymbol{\varepsilon}^{\mathrm{t}}$ is defined as a function of the reversible volume fraction η^{rev} and the transformation strain of fully-oriented martensite $\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}$,

$$\boldsymbol{\varepsilon}^{\mathrm{t}} = \eta^{\mathrm{rev}} \bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}, \quad \bar{\boldsymbol{\varepsilon}}^{\mathrm{t}} \in \bar{\mathcal{P}} = \{\, \bar{\boldsymbol{\varepsilon}}^{\mathrm{t}} : g(\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}) = 0 \,\}. \tag{9}$$

The set $\bar{\mathcal{P}}$ defines the admissible transformation strain tensors characterized by the surface $g(\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}) = 0$ which is expressed in the following form (Sadjadpour and Bhattacharya, 2007),

$$g(\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}) = \Big[(-I_2)^{3/2} - bI_3 - cI_4^3\Big]^{1/3} - a. \tag{10}$$

In Eq. (10), I_2 and I_3 denote the principal invariants of the transformation strain tensor $\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}$ while I_4 denotes a mixed invariant, defined as

$$I_2 = -\frac{1}{2}\mathrm{tr}(\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}})^2, \quad I_3 = \det \bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}, \quad I_4 = \boldsymbol{m} \cdot \bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}\, \boldsymbol{m}, \tag{11}$$

where $\boldsymbol{m}$ is the axis of the transverse isotropy. The parameters a, b and c characterize the shape and size of the surface $g(\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}) = 0$ and are specified as

$$a = \epsilon_{\mathrm{T}}\Big[\frac{3\sqrt{3}}{4(1+\alpha^3)}\Big]^{1/3}, \qquad b = \frac{\sqrt{3}}{6}\frac{9\alpha^3\beta^3 - 7\alpha^3 + 7\beta^3 - 9}{(1+\alpha^3)(1+\beta^3)}, \qquad c = \frac{2\sqrt{3}}{3}\frac{\alpha^3 - \beta^3}{(1+\alpha^3)(1+\beta^3)}, \tag{12}$$

with ϵ_{T} as the maximum transformation strain in tension, α as the tension–compression asymmetry ratio in the direction along the axis of transverse isotropy (i.e., parallel to $\boldsymbol{m}$), and β as the tension–compression asymmetry ratio in the direction perpendicular to the axis of transverse isotropy (i.e., perpendicular to $\boldsymbol{m}$).

It is noteworthy that the deviatoric nature of the transformation strain $\boldsymbol{\varepsilon}^{\mathrm{t}}$ dictates, in accordance with the definition of the direction tensor N_{p}, see Eq. (8), that the permanent strain ε^{p} is also

deviatoric. Models within the present context often postulate that the fatigue-induced inelastic strain evolves in the direction of stress deviator (e.g., Zaki and Moumni, 2007; Kan and Kang, 2010; Xiao and Jiang, 2020). In the present formulation, it can be easily shown that the stress deviator is perpendicular to the surface $g(\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}) = 0$, see Stupkiewicz and Petryk (2013), and thereby, the transformation strain $\boldsymbol{\varepsilon}^{\mathrm{t}}$ depends on the direction of stress deviator. This, however, does not imply that the transformation strain $\boldsymbol{\varepsilon}^{\mathrm{t}}$, and accordingly the permanent strain rate $\dot{\boldsymbol{\varepsilon}}^{\mathrm{p}}$, are colinear with the stress deviator.

Another important aspect to highlight is that the surface $g(\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}) = 0$ and so the transformation strain of fully-oriented martensite $\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}$ remain intact throughout the cyclic transformation. However, the accumulation of the irreversible volume fraction η^{ir} and its impact on the reversible volume fraction η^{rev} result in the contraction of the maximum transformation strain attainable during the phase transformation, see Eqs. (3) and (9).

We now elaborate on the Helmholtz free energy function and the dissipation potential, both customized to incorporate the degradation effects. Assuming an isothermal process, the Helmholtz free energy ϕ is composed of the following contributions: the chemical energy ϕ_{chem}, the elastic strain energy ϕ_{el}, the austenite–martensite interaction energy ϕ_{int}, the energy of the diffuse interface ϕ_{grad}, and the energy contribution ϕ_{deg} related to the pseudoelasticity degradation, i.e.,

$$\begin{aligned}\phi(\boldsymbol{\varepsilon}, \bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}, \boldsymbol{\varepsilon}^{\mathrm{p}}, \eta^{\mathrm{rev}}, \nabla\eta^{\mathrm{rev}}, \eta^{\mathrm{ir}}) = \\ \phi_{\mathrm{chem}}(\eta^{\mathrm{rev}}, \eta^{\mathrm{ir}}) + \phi_{\mathrm{el}}(\boldsymbol{\varepsilon}, \bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}, \boldsymbol{\varepsilon}^{\mathrm{p}}, \eta^{\mathrm{rev}}) + \phi_{\mathrm{int}}(\eta^{\mathrm{rev}}) + \phi_{\mathrm{grad}}(\nabla\eta^{\mathrm{rev}}) + \phi_{\mathrm{deg}}(\eta^{\mathrm{rev}}, \eta^{\mathrm{ir}}). \quad (13)\end{aligned}$$

Among the contributions to the Helmholtz free energy ϕ, only ϕ_{deg} is specific to the present model. The remaining contributions are rather standard and adhere to the non-fatigue model of pseudoelasticity (cf., Stupkiewicz and Petryk, 2013; Rezaee Hajidehi and Stupkiewicz, 2018; Rezaee-Hajidehi et al., 2020), and are formulated as

$$\phi_{\mathrm{chem}}(\eta^{\mathrm{rev}}, \eta^{\mathrm{ir}}) = (1-\eta)\phi_0^{\mathrm{a}} + \eta\phi_0^{\mathrm{m}} = \phi_0^{\mathrm{a}} + \Delta\phi_0\eta, \quad (14)$$

$$\phi_{\mathrm{el}}(\boldsymbol{\varepsilon}, \bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}, \boldsymbol{\varepsilon}^{\mathrm{p}}, \eta^{\mathrm{rev}}) = \mu\,\mathrm{tr}(\boldsymbol{\varepsilon}^{\mathrm{e}}_{\mathrm{dev}})^2 + \frac{1}{2}\kappa(\mathrm{tr}\,\boldsymbol{\varepsilon}^{\mathrm{e}})^2, \quad \boldsymbol{\varepsilon}^{\mathrm{e}} = \boldsymbol{\varepsilon} - \eta^{\mathrm{rev}}\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}} - \boldsymbol{\varepsilon}^{\mathrm{p}}, \quad (15)$$

$$\phi_{\mathrm{int}}(\eta^{\mathrm{rev}}) = \frac{1}{2}H_{\mathrm{int}}(\eta^{\mathrm{rev}})^2, \quad (16)$$

$$\phi_{\mathrm{grad}}(\nabla\eta^{\mathrm{rev}}) = \frac{1}{2}G\nabla\eta^{\mathrm{rev}}\cdot\nabla\eta^{\mathrm{rev}}. \quad (17)$$

Here, $\Delta\phi_0 = \phi_0^{\mathrm{m}} - \phi_0^{\mathrm{a}}$ is the phase transformation chemical energy, μ is the elastic shear modulus and is calculated via applying the Reuss averaging scheme based on the total volume fraction η to the shear moduli of austenite μ_{a} and martensite μ_{m} (i.e., $1/\mu = (1-\eta)/\mu_{\mathrm{a}} + \eta/\mu_{\mathrm{m}}$), κ is the elastic bulk modulus (assumed constant), H_{int} is the parameter that characterizes the material response (softening- or hardening-type) within the transformation regime, and $G > 0$ is the gradient energy

coefficient. Note that the parameter H_{int} can be adapted such that it reflects a loading-dependent material response (typically, a softening-type response in tension and hardening-type response in compression) (e.g., Rezaee-Hajidehi and Stupkiewicz, 2021). However, for simplicity, H_{int} is here considered as a constant parameter. Given that the simulations in this study involve predominantly tensile loading, see Section 3, this simplification does not pose a serious limitation.

On the other hand, the degradation contribution ϕ_{deg} takes the following form

$$\phi_{\mathrm{deg}}(\eta^{\mathrm{rev}}, \eta^{\mathrm{ir}}) = A_{\mathrm{deg}} \eta^{\mathrm{ir}} \eta^{\mathrm{rev}} + \frac{1}{2} H_{\mathrm{deg}} \eta^{\mathrm{ir}} (\eta^{\mathrm{rev}})^2, \tag{18}$$

where A_{deg} and H_{deg} represent the degradation parameters. The energy ϕ_{deg} is specifically tailored to address two primary effects of pseudoelasticity degradation: it accounts for the reduction of the transformation-onset stress (described by the term $A_{\mathrm{deg}} \eta^{\mathrm{ir}} \eta^{\mathrm{rev}}$) and the conversion of the mechanical response towards a hardening-type response (described by the term $\frac{1}{2} H_{\mathrm{deg}} \eta^{\mathrm{ir}} (\eta^{\mathrm{rev}})^2$). In line with the evolution of η^{ir}, Eq. (5), both effects progress exponentially. Note that the approach of incorporating the cyclic degradation effects into the free energy function has been also used in other SMA functional fatigue models in the literature (e.g., Auricchio et al., 2007; Petrini and Bertini, 2020).

Finally, a rate-independent dissipation potential is adopted in the following form

$$D(\dot{\eta}^{\mathrm{rev}}, \eta^{\mathrm{acc}}) = f_{\mathrm{c}}(\eta^{\mathrm{acc}}) |\dot{\eta}^{\mathrm{rev}}|, \tag{19}$$

where $f_{\mathrm{c}}(\eta^{\mathrm{acc}})$, which is called the critical thermodynamic driving force, controls the width of the hysteresis loop in the stress–strain response. To capture the decrease in the hysteresis loop area (i.e., the dissipated energy) during the cyclic loading, the parameter f_{c} is defined in relation to the accumulated volume fraction η^{acc}. Similar to the permanent strain $\boldsymbol{\varepsilon}^{\mathrm{p}}$ and the irreversible volume fraction η^{ir}, Eqs. (5)–(7), f_{c} evolves exponentially as follows

$$f_{\mathrm{c}}(\eta^{\mathrm{acc}}) = f_{\mathrm{c}}^{\mathrm{fin}} + (f_{\mathrm{c}}^{\mathrm{ini}} - f_{\mathrm{c}}^{\mathrm{fin}}) \exp(-C_{\mathrm{f}} \eta^{\mathrm{acc}}), \tag{20}$$

where $f_{\mathrm{c}}^{\mathrm{ini}}$ and $f_{\mathrm{c}}^{\mathrm{fin}}$ represent, respectively, the initial and final values of f_{c} and C_{f} denotes the corresponding evolution rate.

To formulate the incremental energy minimization problem, we derive the time-discrete version of the constitutive equations by employing the backward Euler scheme. Having known the variables related to the previous time step t_n, the variables related to the current time step $t_{n+1} = t_n + \Delta t$ are sought. We begin by approximating the incremental evolution equation for the irreversible volume fraction η^{ir} and the permanent strain $\boldsymbol{\varepsilon}^{\mathrm{p}}$,

$$\Delta t\, \dot{\eta}^{\mathrm{ir}} \approx \Delta \eta^{\mathrm{ir}} = h_{\mathrm{ir}}^{\mathrm{sat}} C_{\mathrm{p}} \exp(-C_{\mathrm{p}} \eta^{\mathrm{acc}}) \Delta \eta^{\mathrm{acc}}, \quad \Delta t\, \dot{\boldsymbol{\varepsilon}}^{\mathrm{p}} \approx \Delta \boldsymbol{\varepsilon}^{\mathrm{p}} = \epsilon_{\mathrm{p}}^{\mathrm{sat}} C_{\mathrm{p}} \exp(-C_{\mathrm{p}} \eta^{\mathrm{acc}}) \Delta \eta^{\mathrm{acc}} \boldsymbol{N}_{\mathrm{p}}, \tag{21}$$

where

$$\eta^{\mathrm{acc}} = \int_0^{t_{n+1}} \Delta \eta^{\mathrm{acc}} \, \mathrm{d}\tau, \quad \Delta \eta^{\mathrm{acc}} = |\Delta \eta^{\mathrm{rev}}|, \quad \Delta \eta^{\mathrm{rev}} = \eta^{\mathrm{rev}} - \eta_n^{\mathrm{rev}}, \tag{22}$$

with η_n^{rev} as the value of the reversible volume fraction from the previous time step t_n. At the same time, the incremental form of the rate-independent dissipation potential is obtained as

$$\Delta D(\Delta\eta^{\mathrm{rev}}, \eta^{\mathrm{acc}}) = f_{\mathrm{c}}(\eta^{\mathrm{acc}})|\Delta\eta^{\mathrm{rev}}|. \tag{23}$$

The solution of the problem is determined via the incremental energy minimization principle (Petryk, 2003; Rezaee-Hajidehi et al., 2020). A global incremental potential Π is defined by summing up the increment of the total Helmholtz free energy $\Delta\Phi$ (where $\Phi = \int_B \phi \mathrm{d}V$), the global dissipation potential $\Delta\mathcal{D}$ (where $\Delta\mathcal{D} = \int_B \Delta D \mathrm{d}V$) and the potential of the external loads $\Delta\Omega$, and is subsequently minimized with respect to the unknowns $\boldsymbol{u}$, $\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}$ and η^{rev}, i.e.,

$$\Pi = \Delta\Phi + \Delta\Omega + \Delta\mathcal{D} \;\rightarrow \min_{\boldsymbol{u}, \bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}, \eta^{\mathrm{rev}}} \tag{24}$$

which is subject to the inequality constraints on the reversible volume fraction η^{rev}, Eq. (3), and to the constraint related to the transformation strain surface, Eq. (9). At the same time, η^{ir} and $\boldsymbol{\varepsilon}^{\mathrm{p}}$, which contribute directly to the minimization problem, are explicitly evaluated from Eq. (21). To provide a clearer idea of the structure of the minimization problem and the underlying constitutive behavior of the model, a simplified 1D version of the model is elaborated in Appendix A.

Fig. 2 showcases the intrinsic stress–strain response predicted by the model under cyclic tensile loading. Two cases are highlighted: the pseudoelasticity degradation effects observed within the first three cycles, relevant to the problem of subloop deformation investigated in this study, and the degradation effects observed within 50 cycles, which provides a more holistic view of the model behavior. Note that the material parameters adopted to generate the intrinsic response in Fig. 2 are the same as those adopted in the main simulations in Section 3.

2.2. Further extensions and finite-element implementation

The model presented in Section 2.1 is now enriched with micromorphic regularization and is made thermomechanically coupled. Both extensions have been thoroughly discussed in our previous works (Rezaee Hajidehi and Stupkiewicz, 2018; Rezaee-Hajidehi et al., 2020). Hence, we only briefly discuss them here.

The purpose of adopting the micromorphic regularization is to facilitate the finite-element implementation of the model by restructuring the minimization problem in a way that the constitutive complexities are transferred to the local level (for instance, at the Gauss points) where they can be treated in a more efficient way. To do so, a new degree of freedom $\breve{\eta}$ is introduced and is coupled with the volume fraction η^{rev} through the following penalization term ϕ_{pen} which is added into the Helmholtz free energy function, see Eq. (13),

$$\phi_{\mathrm{pen}}(\eta^{\mathrm{rev}}, \breve{\eta}) = \frac{1}{2}\chi(\eta^{\mathrm{rev}} - \breve{\eta})^2, \tag{25}$$

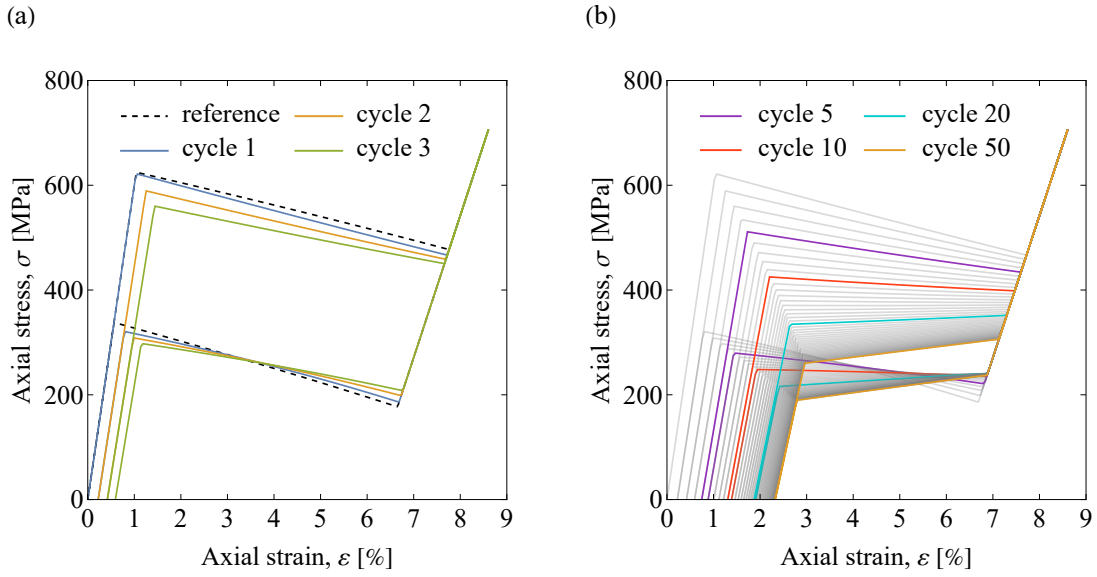

Figure 2: The intrinsic stress–strain response of the model under full-transformation uniaxial-tension cycles: (a) the first three cycles, and (b) the first 50 cycles. The dashed curve in panel (a), denoted as 'reference', represents the pseudoelastic intrinsic response with no degradation effects. The model parameters adopted to produce the intrinsic responses are the same as those in the main simulations, see Section 3.

with χ as the penalty parameter. The gradient energy ϕ_{grad}, see Eq. (17), is then redefined in terms of the gradient of the new variable $\breve{\eta}$, i.e.,

$$\phi_{\text{grad}}(\nabla\breve{\eta}) = \frac{1}{2}G\nabla\breve{\eta}\cdot\nabla\breve{\eta}. \tag{26}$$

Following this modification, the volume fraction η^{rev} can be considered as a local quantity and the respective evolution equation can be solved (together with that of $\bar{\varepsilon}^{\text{t}}$) locally. For further details regarding the micromorphic regularization, interested readers are referred to Forest (2009); Mazière and Forest (2015).

To arrive at a thermomechanically-coupled model, two most important couplings are taken into consideration. First, the chemical energy ϕ_{chem}, Eq. (14), is extended to reflect the effect of temperature on the mechanical response (the Clausius–Clapeyron relation), i.e.,

$$\phi_0(\eta^{\text{rev}},\eta^{\text{ir}},T) = \phi_0^{\text{a}}(T) + \Delta\phi_0(T)\eta, \quad \Delta\phi_0(T) = \Delta s^*(T - T_{\text{t}}), \tag{27}$$

where Δs^* represents the transformation entropy change, T is the temperature, and T_{t} is the transformation equilibrium temperature. Next, the internal heat source $\dot{R}$ is defined to encompass the latent heat of transformation and the heat release by mechanical dissipation, viz.,

$$\dot{R} = \Delta s^* T\dot{\eta}^{\text{rev}} + f_{\text{c}}(\eta^{\text{acc}})|\dot{\eta}^{\text{rev}}|. \tag{28}$$

Eq. (28) is then introduced into the (isotropic) heat conduction equation

$$\varrho_0 c\dot{T} + \nabla \cdot \boldsymbol{Q} = \dot{R}, \quad \boldsymbol{Q} = -\kappa \nabla T, \tag{29}$$

where $\varrho_0 c$ is the specific heat, $\boldsymbol{Q}$ is heat flux and the scalar κ is the heat conduction coefficient. It follows from Eq. (28) that the internal heat generation is influenced during the cyclic phase transformation. This influence is manifested by both the latent heat of transformation and the mechanical dissipation and operates through the reversible volume fraction η^{rev} and the hysteresis parameter f_{c}, cf. Eqs. (3) and (20).

The full thermomechanically-coupled model comprises three global unknown fields: the displacement $\boldsymbol{u}$, the micromorphic variable $\breve{\eta}$ and the temperature T; and two local unknown variables: the reversible volume fraction η^{rev} and the transformation strain $\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}$. Recall that the irreversible volume fraction η^{ir} and the permanent strain $\boldsymbol{\varepsilon}^{\mathrm{p}}$ are explicitly integrated by using Eq. (21). The finite-element discretization of the displacement field $\boldsymbol{u}$ is performed by using 20-noded quadratic hexahedral (Serendipity) elements with reduced Gauss integration rule ($2 \times 2 \times 2$). On the other hand, 8-noded linear hexahedral elements with standard Gauss integration rule ($2 \times 2 \times 2$) are used for $\breve{\eta}$ and T. For the 2D axisymmetric wire problem discussed in Section 3.2, the respective discretizations have been done by 8-noded quadratic elements and 4-noded linear elements. The resulting global–local problem is structured as a nested iterative-subiterative scheme and is solved at both the global and local levels by using the Newton method. Notably, a fully-coupled monolithic scheme is adopted so that the global problem is solved simultaneously with respect to all unknowns.

It is worth noting that the local minimization problem of η^{rev} is non-smooth, in view of the presence of the rate-independent dissipation, see Eqs. (19) and (23). To address this issue, the augmented Lagrangian method is utilized, which handles adeptly both the non-smoothness of the rate-independent dissipation and the inequality constraints on the reversible volume fraction η^{rev}, i.e., $0 \leq \eta^{\mathrm{rev}} \leq 1 - \eta^{\mathrm{ir}}$, see Eq. (3). Moreover, the local problem has an additional constraint to be satisfied, namely the equality constraint of the transformation strain surface $g(\bar{\boldsymbol{\varepsilon}}^{\mathrm{t}}) = 0$, see Eq. (9). The latter is addressed by using a standard Lagrange multiplier method. For brevity, the related technical details are not discussed here, see Stupkiewicz and Petryk (2013).

The model is transformed into a finite-element code using the automatic differentiation tool AceGen (Korelc, 2009; Korelc and Wriggers, 2016), thanks to which the residual vector and the tangent matrix are derived automatically, and thereby, the quadratic convergence of the Newton method is ensured. The simulations are carried out in the finite-element environment AceFEM.

3. Simulations

3.1. Preliminaries

Our modeling study concerns a NiTi specimen subjected to uniaxial tension with subloop loading paths. Two scenarios are explored. First, in line with the experimental study of Tobushi et al. (2003), the subloop deformation behavior of a NiTi wire is analyzed. The loading program in this scenario encompasses three nested subloops with increasing strain amplitudes, as depicted in Fig. 3(a). As shown later, this setup enables us to reproduce neatly the hierarchical return-point memory. Next, we extend our analysis to a NiTi strip, where we elucidate how the subloop behavior is influenced by the complexity of the pattern of propagating instabilities. This scenario is then examined under two additional loading programs, see Fig. 3(b,c). In all simulations, the loading is exerted in a displacement-control mode at a (constant) low strain rate of 1.67×10^{-4} s^{-1}.

The NiTi wire has a diameter of 0.75 mm and a total length of $L_0 = 20$ mm. To facilitate this analysis, the wire is justifiably reduced to a 2D axisymmetric geometry. The corresponding 2D problem is then discretized by a uniform finite-element mesh consisting of equiaxed elements with an edge size of 0.01 mm. This resulted in 76 000 elements and approximately 620 000 degrees of freedom. Meanwhile, the NiTi strip is treated as a full 3D problem. The strip has a thickness of 0.4 mm, a width of 10 mm and a total length of $L_0 = 100$ mm. It is discretized by a uniform mesh consisting of elements with an in-plane edge size of 0.2 mm and a through-thickness size of 0.4 mm (i.e., only one element is used though the thickness). This mesh led to 25 000 elements and nearly 640 000 degrees of freedom. In both problems, the following boundary conditions are imposed. The displacements at the bottom edge of the specimen are fully constrained. At the top edge, the axial displacement δ is prescribed and the lateral displacements are constrained. At the

same time, the temperature at both top and bottom edges is set equal to the ambient temperature, i.e., $T = T_0 = 353$ K, which is the actual ambient temperature maintained during the experiment (Tobushi et al., 2003). Finally, the heat convection effect is neglected.

The model parameters adopted in the simulations are summarized in Tab. 1. Except for the gradient energy parameter G, all the model parameters are identical in the wire and strip problems. The parameter G sets the length-scale associated with the phase transformation front and can be linked to the geometry and micromechanical characteristics (Sedmák et al., 2016; Stupkiewicz et al., 2021). Thus, G takes different values in each problem. First, an assumption ought to be made regarding the theoretical thickness of the macroscopic interface, λ. Subsequently, G is determined through the analytical relation $G = -H_{\mathrm{int}}\lambda^2/\pi^2$, which is derived from the solution of the 1D small-strain model of pseudoelasticity (Rezaee Hajidehi and Stupkiewicz, 2018). The identification procedure for the remaining model parameters which are unrelated to fatigue has been thoroughly discussed in our recent study (Rezaee-Hajidehi and Stupkiewicz, 2023), see Section 2.3 and Appendix E therein, and is not repeated here.

Identification of some fatigue-related parameters is guided by the indications obtained from the structural stress–strain response from the experiment, see Fig. 1(a). These include the significant decrease in the level of the upper stress plateau during the hierarchical subloop deformation and the value of the remnant strain at the end of the experiment. Accordingly, the parameters $A_{\mathrm{deg}} = -45$ MPa, $\epsilon_{\mathrm{r}}^{\mathrm{sat}} = 0.4\epsilon_{\mathrm{T}} = 2.4\%$ (recall that ϵ_{T} denotes the maximum transformation strain, Eq. (12)) and $C_{\mathrm{p}} = 0.05$ have been calibrated to produce similar effects. We, however, acknowledge that there exists a degree of uncertainty in the identification of the remaining parameters, for which we lack definitive experimental evidence. With this in mind, the parameters $H_{\mathrm{deg}} = 40$ MPa, $f_{\mathrm{c}}^{\mathrm{fin}} = 2$ MPa, $C_{\mathrm{f}} = C_{\mathrm{p}} = 0.05$ and $h_{\mathrm{ir}}^{\mathrm{sat}} = 0.4$ are selected such that the changes in the intrinsic stress–strain response under a large number of loading cycles (in particular, as it concerns the transition to a hardening-type response, decrease in the hysteresis loop area and decrease in the extent of the transformation strain) are in a reasonable qualitative agreement with those reported in other experimental and modeling studies (e.g., Eggeler et al., 2004; Wang et al., 2008; Delville et al., 2011; Morin et al., 2011; Petrini and Bertini, 2020). The intrinsic response of the model resulting from the adopted parameters is illustrated in Fig. 2.

It is worth noting that in all the simulations, as a way to trigger the phase transformation instability, a geometric imperfection in the form of a slight indent is applied to the specimen. The indent is located at a distance equal to the diameter/width of the wire/strip from its lower end.

3.2. Simulation results: NiTi wire

The results pertaining to the subloop behavior of the NiTi wire are presented in Figs. 4 and 5. The phase transformation evolution in Fig. 4(a) and TRIP evolution in Fig. 4(b) are displayed via,

Table 1: Model parameters adopted in the simulations.

Category	Parameter		Value
Elasticity	κ	Bulk modulus	130 GPa
	μ_{a}	Shear modulus for austenite	21 GPa
	μ_{m}	Shear modulus for martensite	9 GPa
Martensitic phase transformation	Δs^*	Chemical energy of transformation	0.24 MPa/K
	T_{t}	Transformation equilibrium temperature	222 K
	$f_{\mathrm{c}}^{\mathrm{ini}}$	Hysteresis loop parameter (initial)	10 MPa
	H_{int}	Austenite–martensite interaction parameter	-10.5 MPa
	ϵ_{T}	Maximum tensile transformation strain	6%
	α	Tension–compression asymmetry ratio	1.4
	β	Transverse isotropy parameter	1.0
Macroscopic transformation front	G	Gradient energy parameter (wire problem)	0.04 MPa mm^2
	G	Gradient energy parameter (strip problem)	0.4 MPa mm^2
	χ	Micromorphic regularization parameter	100 MPa
Heat transfer	ϱc_0	Specific heat	2.86 MJ/(m^{3}K)
	κ	Heat conductivity	18 W/(m K)
TRIP	A_{deg}	Pseudoelasticity degradation parameter	-45 MPa
	H_{deg}	Pseudoelasticity degradation parameter	40 MPa
	$\epsilon_{\mathrm{p}}^{\mathrm{sat}}$	Permanent strain saturation value	0.4 $\epsilon_{\mathrm{T}} = 2.4\%$
	$h_{\mathrm{ir}}^{\mathrm{sat}}$	Irreversible volume fraction saturation value	0.4
	$f_{\mathrm{c}}^{\mathrm{fin}}$	Hysteresis loop parameter (final)	2 MPa
	C_{p}	Degradation rate	0.05
	C_{f}	Hysteresis loop degradation rate	0.05

respectively, the distribution of the reversible volume fraction η^{rev} and irreversible volume fraction η^{ir}. Note that, for a more natural visualization, the results of the 2D axisymmetric wire are post-processed and presented in a 3D configuration. As anticipated, the transformation initiates at the position of the geometric imperfection. Throughout the entire loading stage of the global cycle (hereinafter, to avoid confusion with the subloops, we use the term 'global'), the transformation maintains a single propagating front. Interestingly, while the front appears to be a flat (and visibly diffuse) interface in the 3D-wire configuration (e.g., Watkins et al., 2018), it takes on a spherical-shaped appearance (or 'cone-shaped' as described in Sedmák et al. (2016); Sedlák et al. (2021)), as can be conceived from the corresponding pattern in the axisymmetric planes (not shown here). During the global unloading, the backward transformation commences from the wire's central part. As shown in Fig. 4(b) and discussed below, the highest amount of irreversible volume fraction η^{ir}, thus the highest TRIP, is accumulated within the central part, making it a favorable site for the nucleation of the austenitic band. At the same time, due to a slight asymmetry in the distribution of η^{ir} with respect to the wire's midpoint, the two evolved fronts do not propagate concurrently. More specifically, first, the top front reaches the boundary and annihilates, after which the bottom front follows suit.

Within each subloop path, the front retreats downward during unloading and advances upward during reloading. This cyclic movement prompts the material points inside the front's sweeping zone to undergo backward-then-forward transformation, and thereby, gives rise to the accumulation of TRIP within the sweeping zone, while the material points beyond it remain unaffected. Given that the loading program adheres to a fixed nominal mean strain (set at $\bar{\varepsilon} = 4.5\%$, which corresponds to the front's proximity to the wire's midpoint) but an increasing strain amplitude, see Fig. 3(a), the sweeping zone expands successively from subloop 1 to subloop 3, and at the same time, the sweeping zone of each subloop encompasses that of the previous one. This therefore results in the highest concentration of TRIP within the central part of the wire and its step-wise decreasing trend as it moves away from it, as can be clearly seen in Fig. 4(b).

The hierarchical return-point memory, which is an outcome of the cyclic traversal of the front across the boundaries of the swept zones, is correctly reproduced in the structural stress–elongation ($\bar{\sigma}$–$\bar{\varepsilon}$) response in Fig. 5. The reproduced feature is in a reasonable agreement with the experimental result of Tobushi et al. (2003), see Fig. 1 and the accompanying discussion. In view of the exponential nature of the pseudoelasticity degradation effects, the reduction in the level of the upper stress plateau is at the highest within the first level of hierarchy (of about $\Delta\bar{\sigma} = 21$ MPa) and diminishes to its lowest within the last level of hierarchy (of about $\Delta\bar{\sigma} = 17$ MPa). It is worth noting that in this scenario, where the strain rate corresponds to nearly isothermal conditions (i.e., the temperature variation lies within the range of -2 K to 2 K), the stress, upon reaching the

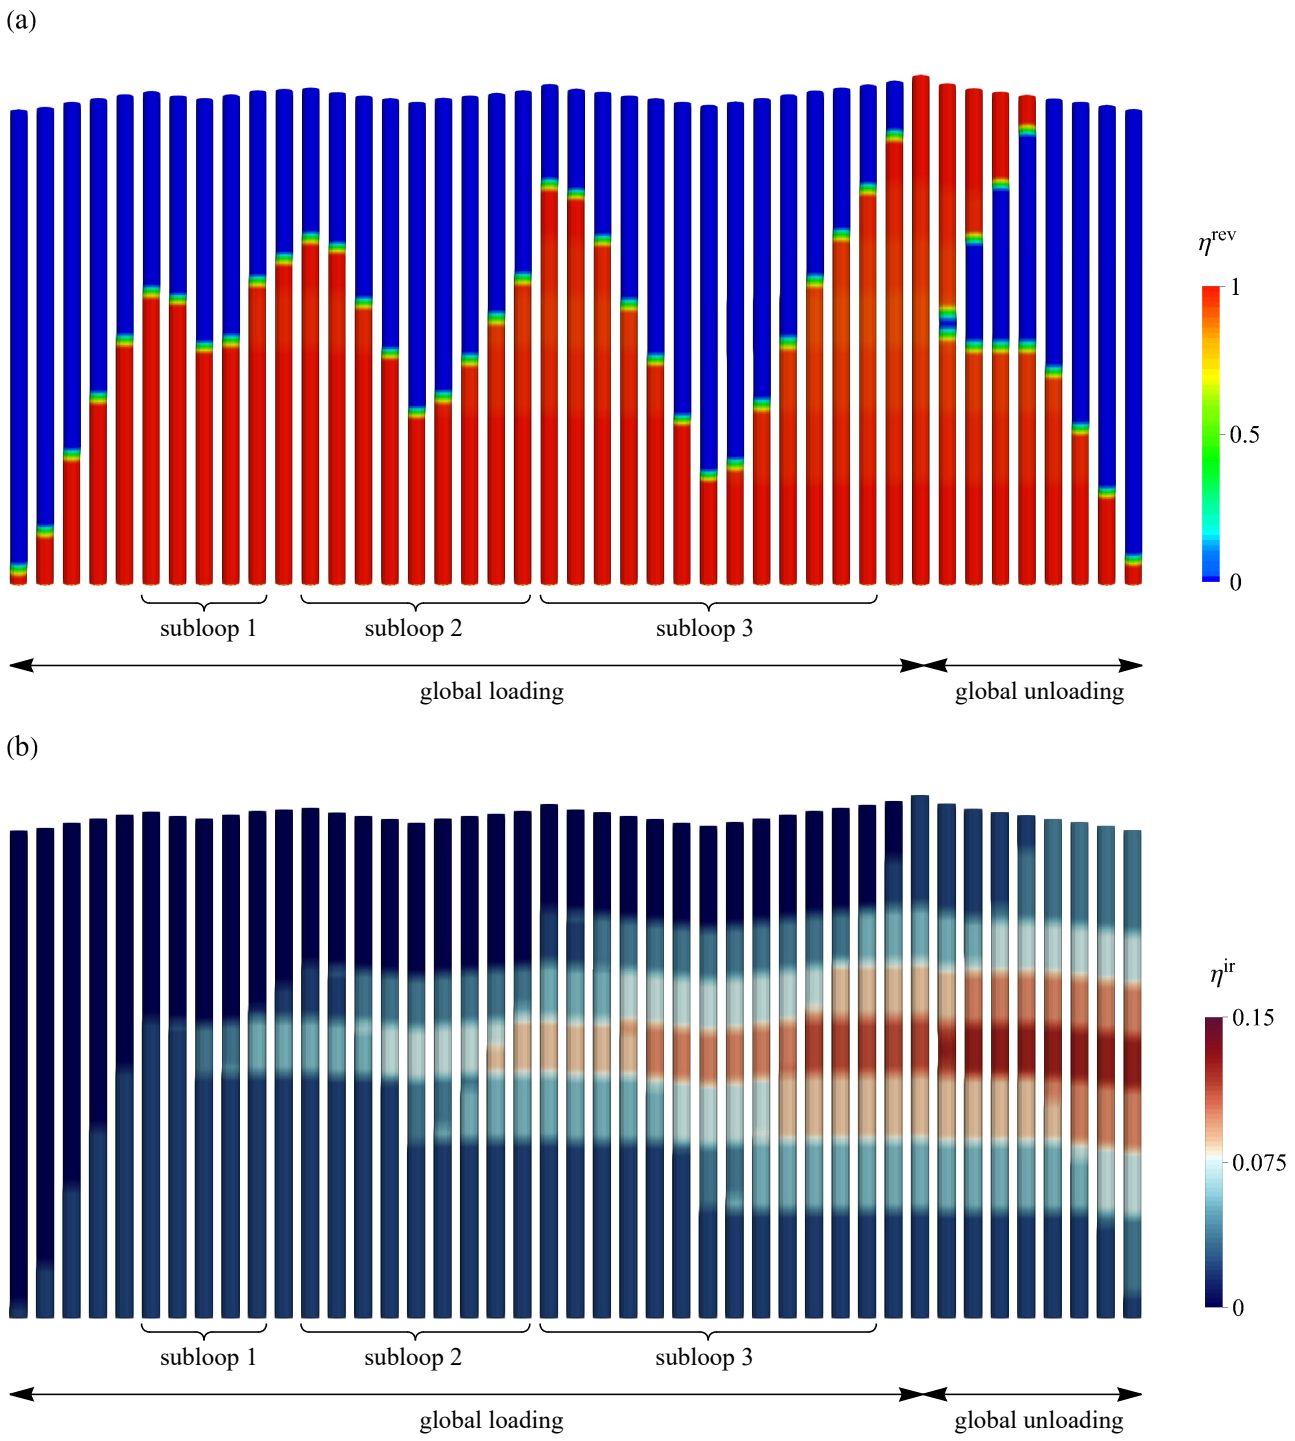

Figure 4: NiTi wire subjected to loading program 1: snapshots of (a) reversible volume fraction η^{rev} and (b) irreversible volume fraction η^{ir}.

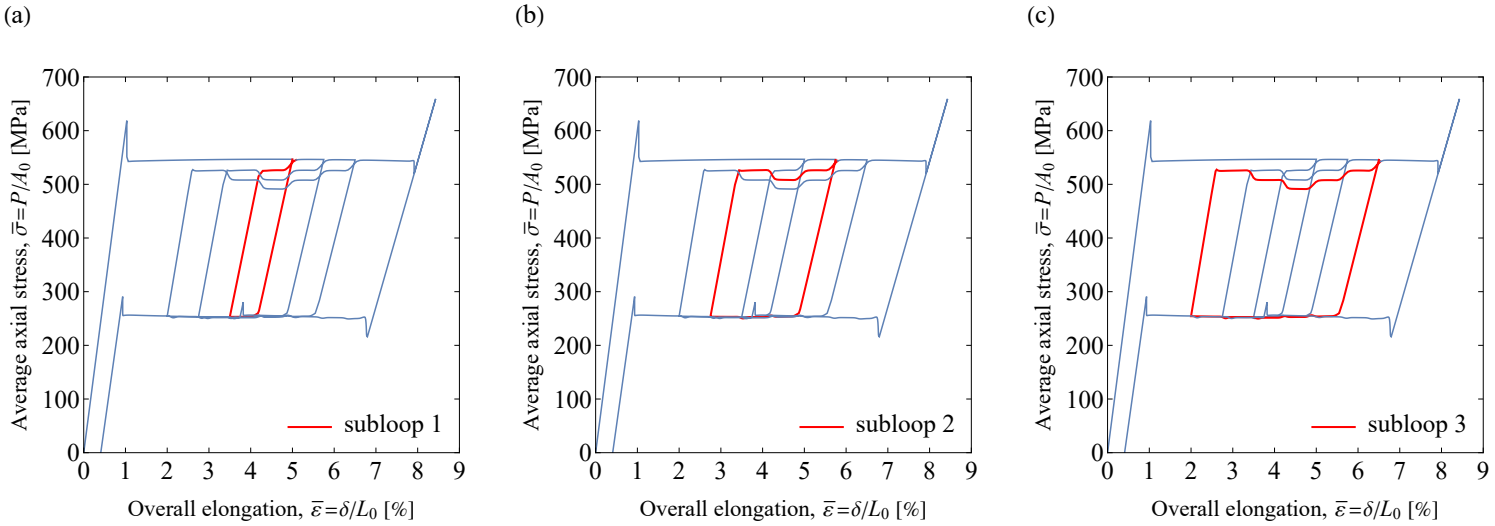

Figure 5: NiTi wire subjected to loading program 1: structural stress–elongation ($\bar{\sigma}$–$\bar{\varepsilon}$) response. The average axial stress $\bar{\sigma}$ is calculated as the reaction force P over the initial cross-section area A_0.

return-point, appears to catch up closely with the corresponding stress plateau before applying the subloop. As shown in Section 3.3 and also observed in the experiments (Doraiswamy et al., 2011; Takeda et al., 2012), such a close catching up does not occur when thermal effects are at play.

A notable observation from the experimental curve in Fig. 1(a) is the absence of the return-point memory during the unloading stages of the subloops. Instead, the lower stress plateau seems to shift downward from one subloop to the next. Anyway, no attempt was made to adjust the material parameters to replicate the observed behavior, which is, however, present in the results of NiTi strip reported in Section 3.3.

3.3. Simulation results: NiTi strip

We begin this section by analyzing the NiTi strip under loading program 1. The primary aim is to examine the subloop behavior in a notably more involved scenario than the NiTi wire discussed earlier, arising mainly from a more complex transformation pattern and heightened thermal effects. The simulation results are presented in Figs. 6 and 7. A quick look at Fig. 7 immediately indicates that the return-point memory is only observable in the trajectories that lead to the global stress plateau, while the hierarchical return-point memory is lost. This is undoubtedly an outcome of the nontrivial pattern of phase transformation and resulting TRIP distribution within the strip. In contrast to the NiTi wire, where a single phase transformation front remained active during all subloops, the strip features multiple transformation fronts, each presenting a less predictable pattern of activation. Below, we provide a more detailed account of the unfolding events.

The phase transformation initiates by the nucleation of a single martensite band at the location of the geometric imperfection. As the overall elongation reaches about $\bar{\varepsilon} = 3\%$, another marten-

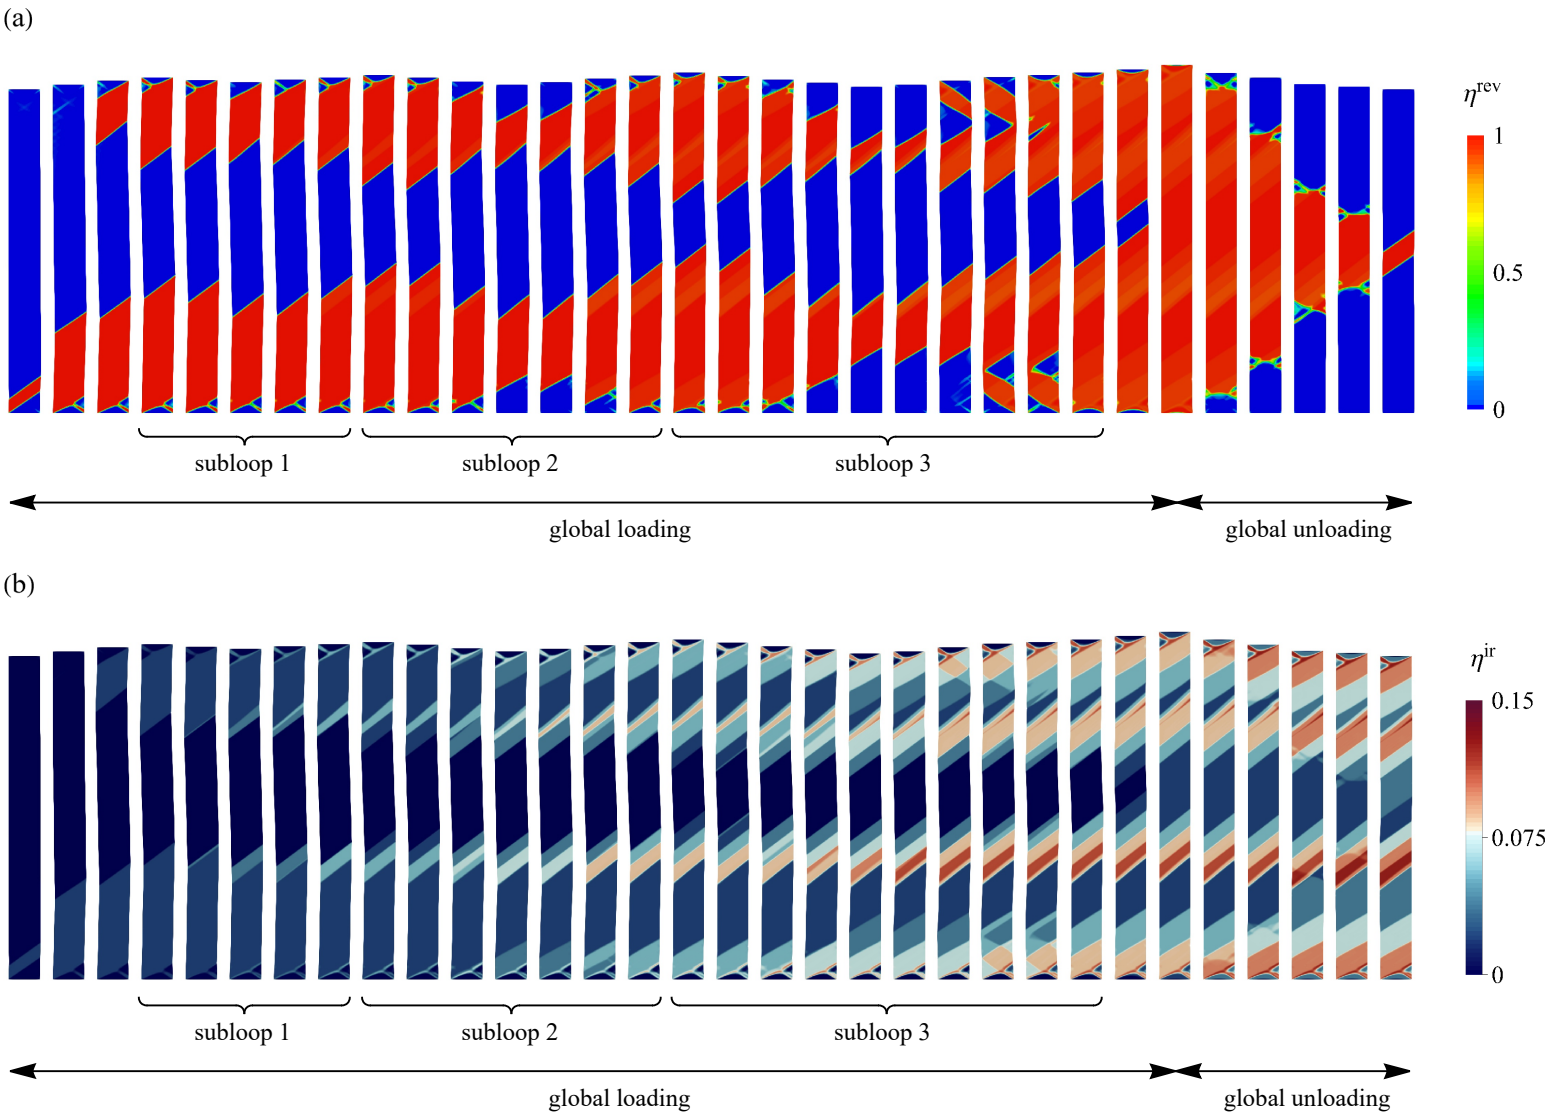

Figure 6: NiTi strip subjected to loading program 1: snapshots of (a) reversible volume fraction η^{rev} and (b) irreversible volume fraction η^{ir}.

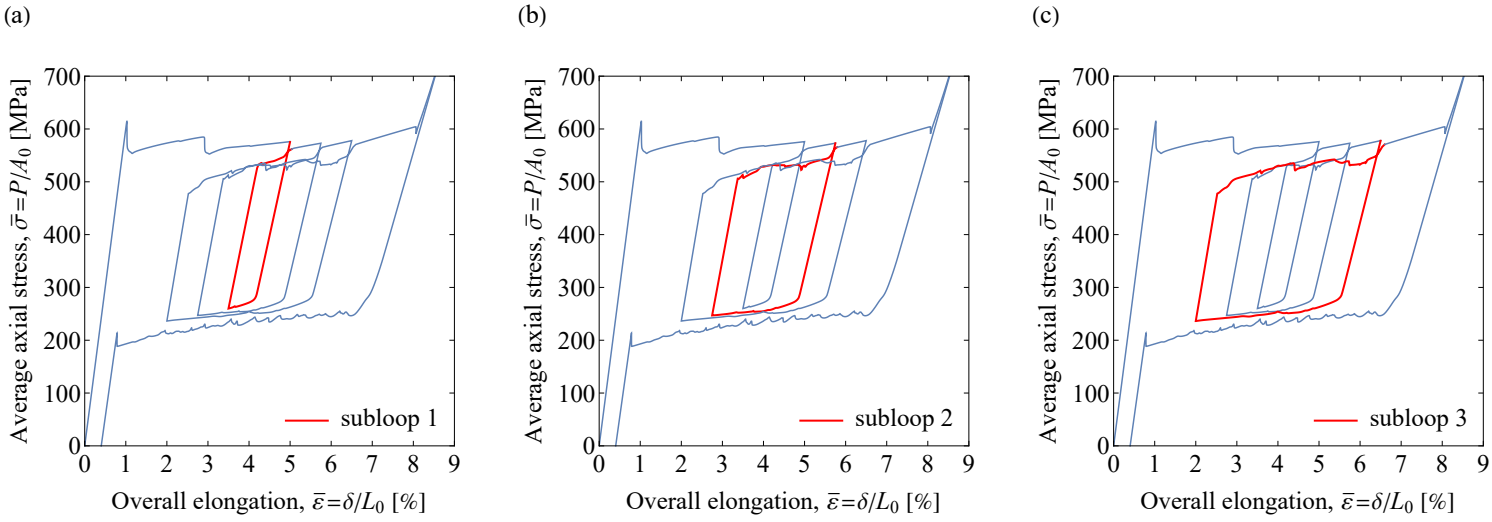

Figure 7: NiTi strip subjected to loading program 1: structural stress–elongation ($\bar{\sigma}$–$\bar{\varepsilon}$) response.

site band emerges at the opposite end, and as the loading progresses, both transformation fronts propagate towards each other. This non-synchronous double nucleation is commonly observed in the experiment of NiTi specimens at relatively low strain rates (e.g., Shaw and Kyriakides, 1997b; Zhang et al., 2010; Bechle and Kyriakides, 2014). Within subloop 1, the two fronts exhibit a short back-and-forth movement, manifesting a clear return-point memory in the $\bar{\sigma}$–$\bar{\varepsilon}$ response in Fig. 7(a). During subloop 2, not only the hitherto active fronts but also the fronts near the boundaries become engaged in the transformation evolution. As a consequence, TRIP is induced via all fronts. This behavior is reflected in the $\bar{\sigma}$–$\bar{\varepsilon}$ response which takes on an irregular appearance characterized by few sudden stress changes, thus spoiling the return-point memory in the inner part (Fig. 7(b)). A similar process recurs within subloop 3, albeit with a more complex phase transformation evolution during the reloading stage and also more distinct stress events in the mechanical response. During the global unloading, the backward transformation proceeds predominantly in a criss-cross mode, which persists until an overall elongation of about $\bar{\varepsilon} = 3\%$. Subsequently, the fronts reconfigure into sharp inclined interfaces that move towards each other until the complete annihilation of the (reversible) martensite domain. It is worth remarking that the distribution of the irreversible volume fraction η^{ir} within the entire strip at the end of the global unloading remains consistent with that at the end of the global loading, while its magnitude increases uniformly.

Upon inspecting the return-point memory in Fig. 7, a slight difference can be noticed concerning the level of the global stress plateau before and after a subloop path. This difference stems from the thermal effects. Specifically, compared to the NiTi wire, a more pronounced temperature variation is produced across the specimen during the forward transformation (for instance, of about 10 K immediately before subloop 1), resulting in a more visible thermal hardening that sustains a higher

stress for the propagation of the front. Within the subloop path, the transformation latent heat is initially absorbed during the backward transformation (self-cooling) and is subsequently released when the forward transformation resumes (self-heating). Accordingly, as the front reaches the pristine material, the temperature variation across the specimen is reduced compared to the state before the subloop (for instance, of about 5 K immediately after subloop 1). Thereby, thermal hardening diminishes, necessitating a lower stress for interface propagation. Note also that as a result of the cyclic transformation of the material points, a smaller martensite volume fraction is transformed during the subloop reloading compared to the state before the subloop, and this contributes to the reduction of the latent heat generation (Iadicola and Shaw, 2002).

We now proceed with the analysis of the NiTi strip under two additional loading programs, one consisting of nested subloops with decreasing strain amplitudes, i.e., subloops are applied in a reverse order compared to loading program 1, and the other consisting of three equally-spaced distinct subloops with a constant strain amplitude, see Fig. 3(b,c). The corresponding results are shown in Figs. 8, 9 and 10. The comparison of the snapshots of the reversible volume fraction η^{rev} in the two additional cases to those of loading program 1 reveals noticeable morphological differences, which are beyond the differences arising solely from the loading-dependent transformation evolution pathways. The differences mainly concern the varying number of martensite domains formed during the global loading stage and the activation pattern of the fronts within the subloops. More specifically, unlike loading program 1, loading programs 2 and 3 exhibit only two martensite domains during the global loading. In loading program 2, all four fronts remain consistently active within all subloops, resulting in a clear demonstration of the hierarchical return-point memory in the $\bar{\sigma}$–$\bar{\varepsilon}$ response, as shown in Fig. 10(a). In loading program 3, however, while the involvement of the fronts near the boundaries is eye-catching within subloop 1, overall, the interior fronts are prominently active. In this case, the front sweeping zones in the subloops do not interact with each other (as can be also recognized from the snapshots of η^{ir} in Fig. 9), and the resulting subloops are independent, see Fig. 10(b). During the global unloading, all cases show a similar transformation evolution pattern.

We conclude this discussion by addressing TRIP accumulation within the strip in relation to the loading program. Similar to the martensitic transformation, TRIP exhibits characteristics that are specific to the applied loading program. Given that loading programs 1 and 2 have a reverse arrangement of the subloops but are otherwise identical, one would intuitively expect that the resulting TRIP accumulations, in terms of both the pattern and the intensity, would be the same after applying all the three subloops. A comparison of the snapshots of the irreversible volume fraction η^{ir} (Figs. 6 and 8) indeed confirms that TRIP hotspots in these two cases are located in nearly the same regions, with two hotspots near the boundaries and two within the interior of the strip, corresponding to the regions with the highest activity of the fronts. Yet, minor discrepancies

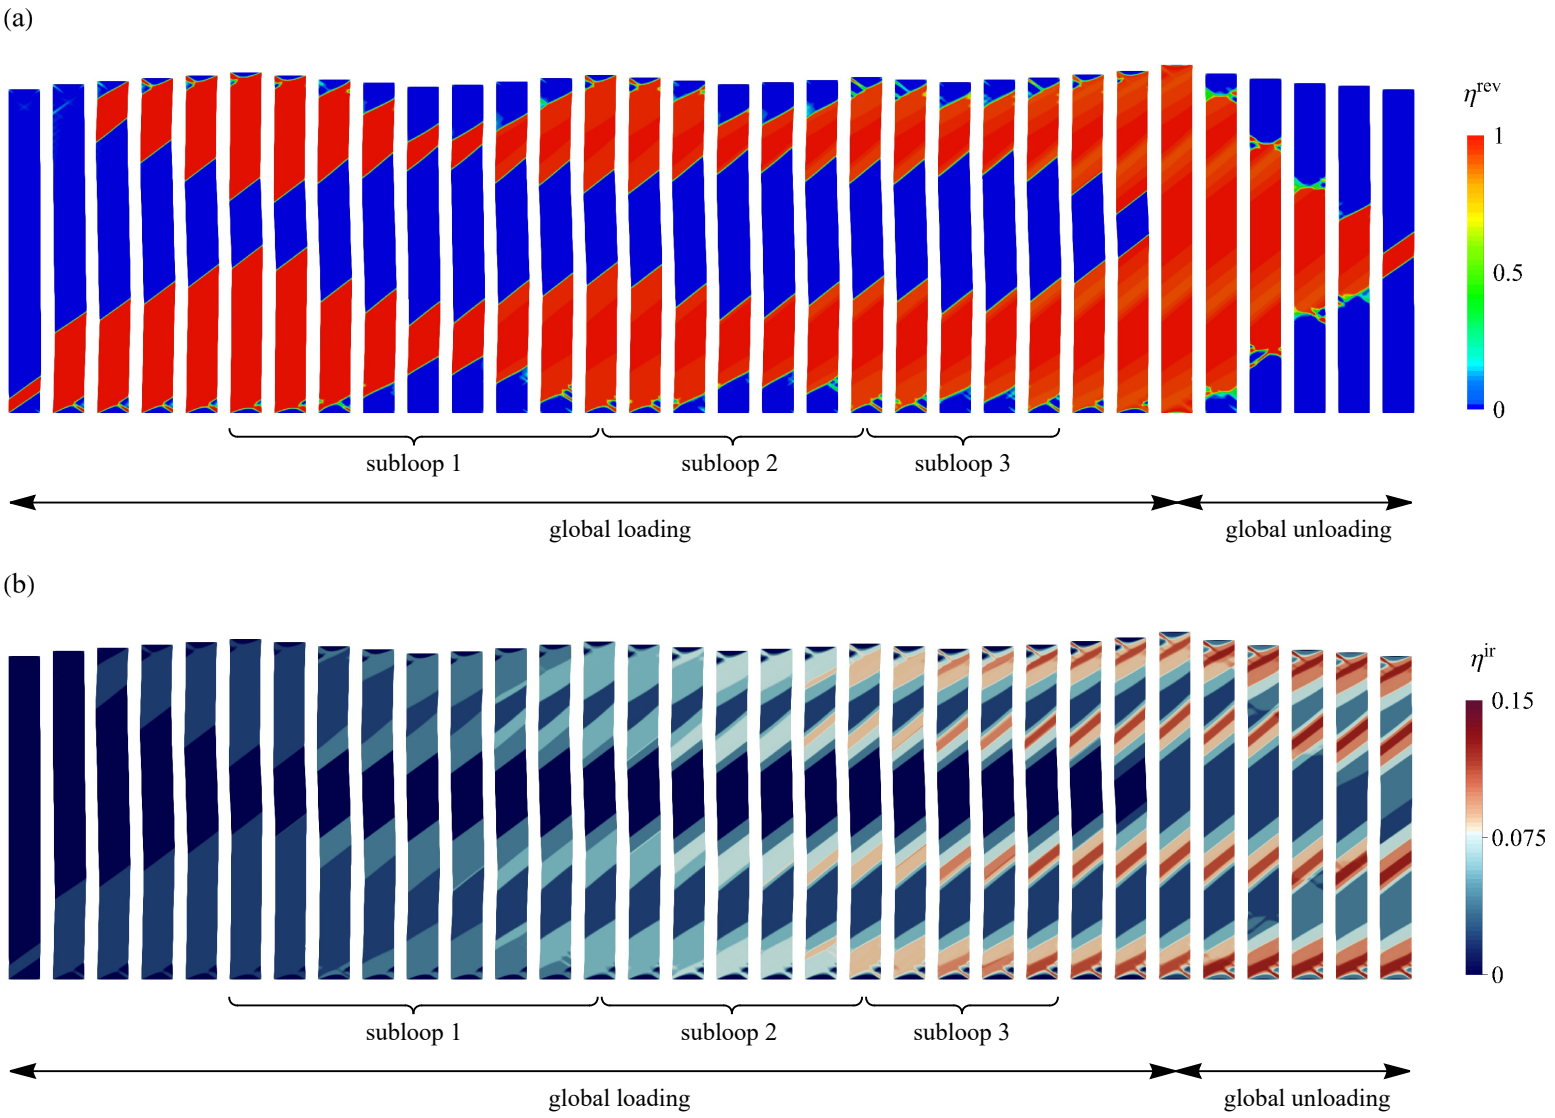

Figure 8: NiTi strip subjected to loading program 2: snapshots of (a) reversible volume fraction η^{rev} and (b) irreversible volume fraction η^{ir}.

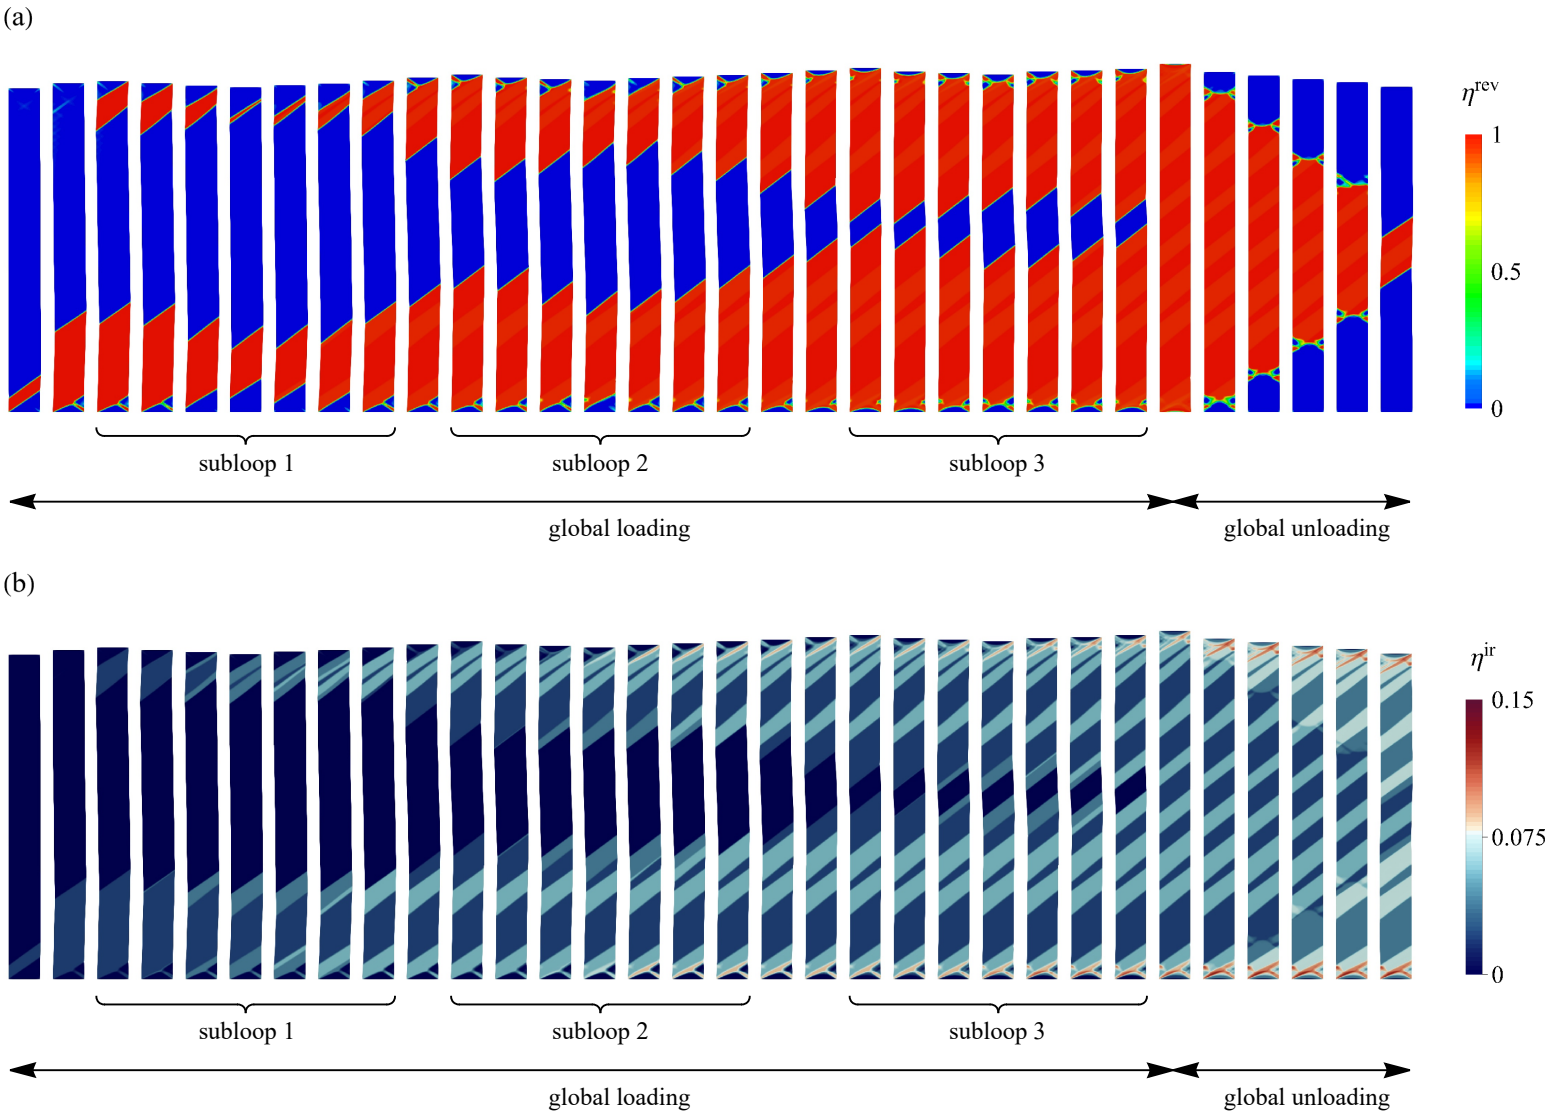

Figure 9: NiTi strip subjected to loading program 3: snapshots of (a) reversible volume fraction η^{rev} and (b) irreversible volume fraction η^{ir}.

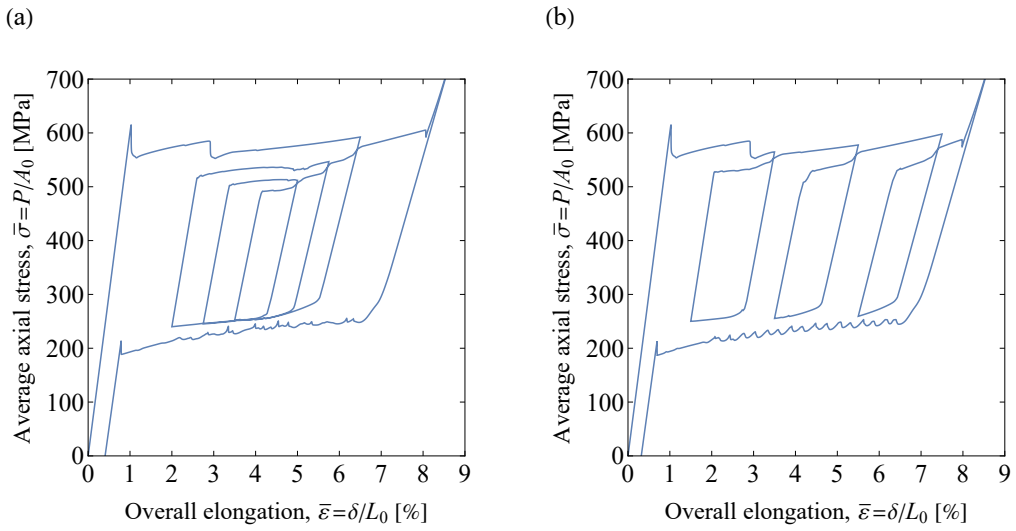

Figure 10: Structural stress–elongation ($\bar{\sigma}$–$\bar{\varepsilon}$) response of NiTi strip subjected to (a) loading program 2 and (b) loading program 3.

can be observed, particularly concerning the intensity of TRIP within the hotspot regions. On the other hand, loading program 3 demonstrates a rather distinct TRIP accumulation characterized by several regions with mild intensity within the interior and localized hotspots near the boundaries. As previously noted, this particular TRIP distribution results from the lack of interaction among the fronts sweeping zones of the independent subloops. As a summary of this discussion, Fig 11 compares the distribution of η^{ir} along the entire length of the strip for various loading programs.

4. Conclusion

The phenomenon of return-point memory that appears during the subloop deformation of pseudoelastic SMA is an outcome of the interaction between the structural instabilities of phase transformation and the degradation of functional properties. It seems that this crucial aspect has been generally overlooked in existing modeling approaches, thus motivating the present work to address this gap. A phenomenological model of functional fatigue is developed for this purpose, which branches from our previous gradient-enhanced model of pseudoelasticity. The main goal of our study is to demonstrate, through modeling the return-point memory, how the instabilities and functional fatigue interact. We first examine an illustrative example of a NiTi wire subjected to nearly isothermal uniaxial tension with nested subloops. The obtained results clearly correlate with the experimental observations of Tobushi et al. (2003), especially regarding the hierarchical return-point memory. The study is then extended to a more involved example of a NiTi strip, where a detailed analysis is performed by examining three different loading programs. The corresponding results underline the intertwined evolution of the phase transformation and TRIP, its relation to

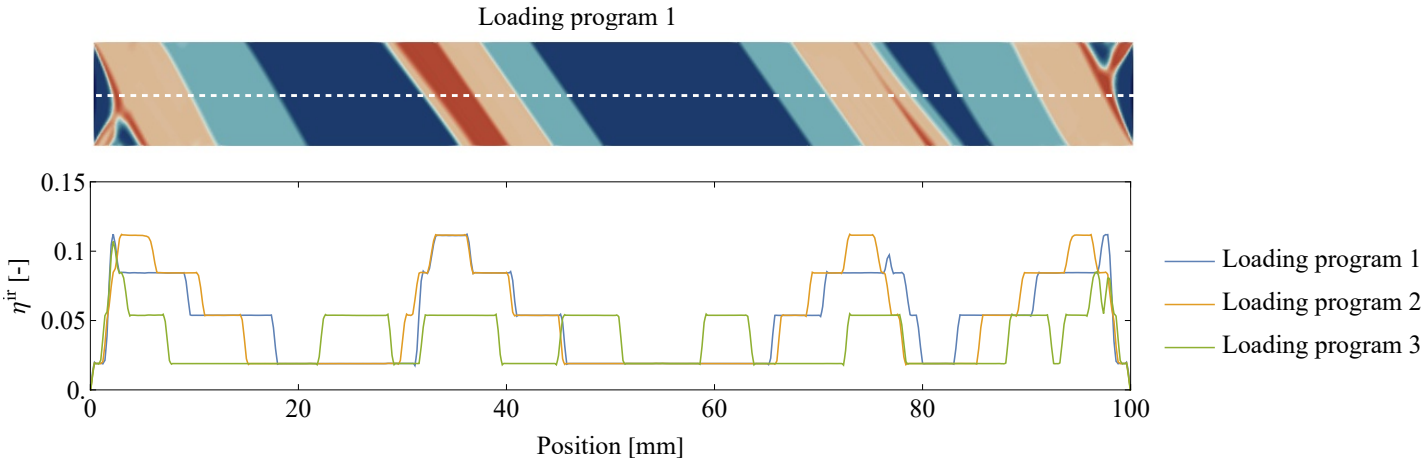

Figure 11: Distribution of the irreversible volume fraction η^{ir} along the entire length of the strip (taken in the reference configuration) at the end of the global loading stage. The graphs correspond to the midsection of the strip, as indicated by the white dashed curve overlaid on the snapshot.

the applied loading program, and its implications on the phenomenon of the return-point memory. In addition, the results hint at the visible contribution of the thermomechanical coupling effects.

Appendix A. A simplified 1D demonstration of the model

In this appendix, we derive the governing equation of the transformation stress for a simplified isothermal 1D model. In 1D setting, the model features four variables, namely the total strain $\varepsilon = \nabla u$, the reversible volume fraction η^{rev}, the irreversible volume fraction η^{ir} and the permanent strain ε^{p}. The Helmholtz free energy is thus expressed as follows

$$\phi(\varepsilon, \varepsilon^{\mathrm{p}}, \eta^{\mathrm{rev}}, \eta^{\mathrm{ir}}) = \phi_{\mathrm{chem}}(\eta^{\mathrm{rev}}, \eta^{\mathrm{ir}}) + \phi_{\mathrm{el}}(\varepsilon, \varepsilon^{\mathrm{p}}, \eta^{\mathrm{rev}}) + \phi_{\mathrm{int}}(\eta^{\mathrm{rev}}) + \phi_{\mathrm{deg}}(\eta^{\mathrm{rev}}, \eta^{\mathrm{ir}}) + I(\eta^{\mathrm{rev}}), \quad \text{(A.1)}$$

where the indicator function I pertains to the inequality constraints on the reversible volume fraction η^{rev} ($I = 0$ if $0 < \eta^{\mathrm{rev}} < 1 - \eta^{\mathrm{ir}}$ and $I = \infty$ otherwise). Note that the gradient energy associated with the austenite–martensite diffuse interface, ϕ_{grad}, is disregarded here.

The elastic strain energy ϕ_{el} is formulated as

$$\phi_{\mathrm{el}}(\varepsilon, \varepsilon^{\mathrm{p}}, \eta^{\mathrm{rev}}) = \frac{1}{2} E(\varepsilon - \varepsilon^{\mathrm{t}} - \varepsilon^{\mathrm{p}})^2, \quad \varepsilon^{\mathrm{t}} = \eta^{\mathrm{rev}} \epsilon_{\mathrm{T}}, \tag{A.2}$$

where E is the Young's modulus (for simplicity, E is assumed constant and independent of η) and the constant ϵ_{T} is the maximum transformation strain. The remaining components of the free energy, as well as the dissipation potential, are identical to those of the general 3D model, see Eqs. (14), (16), (18) and Eq. (23). Moreover, the evolution equations for the permanent strain ε^{p} and the irreversible volume fraction η^{ir} are postulated as (cf. Eq. (5))

$$\eta^{\mathrm{ir}} = h_{\mathrm{ir}}^{\mathrm{sat}}(1 - \exp(-C_{\mathrm{p}} \eta^{\mathrm{acc}})), \quad \varepsilon^{\mathrm{p}} = \epsilon_{\mathrm{p}}^{\mathrm{sat}}(1 - \exp(-C_{\mathrm{p}} \eta^{\mathrm{acc}})). \tag{A.3}$$

For a given total strain ε, the volume fraction η^{rev} can be determined by minimizing the local potential $\pi = \Delta\phi + \Delta D$, see Eq. (24). It is immediate to see that the local potential π is non-smooth, due to the presence of the rate-independent dissipation ΔD and the indicator function I. In line with Rezaee Hajidehi and Stupkiewicz (2018), the minimization of π with respect to η^{rev} is written as a differential inclusion, given by

$$f_{\eta^{\mathrm{rev}}} \in \partial_{\eta^{\mathrm{rev}}} \bar{D}(\eta^{\mathrm{rev}}, \eta^{\mathrm{acc}}) \tag{A.4}$$

where $\bar{D} = \Delta D + I$ encompasses the non-smooth components of π and $f_{\eta^{\mathrm{rev}}}$ is the thermodynamic driving force associated with η^{rev} and is expressed as

$$f_{\eta^{\mathrm{rev}}} = -\left(\frac{\partial \phi}{\partial \eta^{\mathrm{rev}}} + \frac{\partial \phi}{\partial \varepsilon^{\mathrm{p}}} \frac{\partial \varepsilon^{\mathrm{p}}}{\partial \eta^{\mathrm{rev}}} + \frac{\partial \phi}{\partial \eta^{\mathrm{ir}}} \frac{\partial \eta^{\mathrm{ir}}}{\partial \eta^{\mathrm{rev}}} \right). \tag{A.5}$$

During the forward/backward transformation, i.e., when the bound constraints are inactive, the inclusion (A.4) yields

$$f_{\eta^{\mathrm{rev}}} = \pm f_{\mathrm{c}}, \tag{A.6}$$

and gives the following equation for the transformation stress $\sigma_{\pm}^{\mathrm{t}}$ (σ_{+}^{t} for the forward transformation and σ_{-}^{t} for the backward transformation),

$$\sigma_{\pm}^{\mathrm{t}} = \frac{\Delta\phi_0 k_1 \pm f_{\mathrm{c}} + H_{\mathrm{int}} \eta^{\mathrm{rev}} + A_{\mathrm{deg}} k_2 + H_{\mathrm{deg}} \eta^{\mathrm{rev}} k_3}{k_4}, \tag{A.7}$$

where f_{c} is defined in Eq. (20) and k_i are expressed as

$$k_1 = 1 + \frac{\partial \eta^{\mathrm{ir}}}{\partial \eta^{\mathrm{rev}}}, \quad k_2 = \eta^{\mathrm{ir}} + \eta^{\mathrm{rev}} \frac{\partial \eta^{\mathrm{ir}}}{\partial \eta^{\mathrm{rev}}}, \quad k_3 = \eta^{\mathrm{ir}} + \frac{1}{2} \eta^{\mathrm{rev}} \frac{\partial \eta^{\mathrm{ir}}}{\partial \eta^{\mathrm{rev}}}, \quad k_4 = \epsilon_{\mathrm{T}} + \frac{\partial \varepsilon^{\mathrm{p}}}{\partial \eta^{\mathrm{rev}}}. \tag{A.8}$$

It is important to highlight that the necessary condition for the minimum of π with respect to η^{rev}, which leads to the transformation criteria (A.7), is not computed in a standard manner. This

arises as a result of the state-dependence of the dissipation potential D, i.e., the dependence of f_c on the accumulated volume fraction η^{acc}, see Eq.(20). Having the minimization problem formulated in rates (not shown here), it becomes apparent that f_c is treated as constant when evaluating the necessary condition for the rate $\dot{\eta}^{rev}$. In the incremental setting, to maintain consistency with the rate-problem, the increment of the volume fraction, $\Delta\eta^{rev}$, present in the current unknown $\eta^{rev} = \Delta\eta^{rev} + \eta_n^{rev}$ is distinguished from the increment upon which the evolution equation for f_c rely. Despite the two increments coincide, the latter is considered as constant when evaluating the necessary condition (it should be remarked that the extra differentiation terms that result from a non-constant f_c would only marginally contribute to the results). Accordingly, the minimization problem here does posses the structure of a quasi-optimization problem and not a genuine optimization problem. To avoid the complexity in the model presentation, this issue is not elaborated here. For more details, interested readers are referred to Tůma et al. (2016).
